AN-09 How mixed-sex mammal groups decide and lead

The structural dynamics of mixed-sex mammalian societies present a profound evolutionary puzzle: how do distinct individuals, constrained by overlapping but frequently competing biological imperatives, coordinate collective actions, allocate resources, and resolve intragroup conflicts? Understanding collective decision-making, consensus formation, and leadership requires synthesizing decades of field observations, high-resolution geospatial tracking data, and complex mathematical modelling. For species that rely on stable, long-term social groups, the evolutionary benefits of cohesion—such as predator defence, optimized resource acquisition, and enhanced infant survival—must constantly be weighed against the inherent costs of consensus, which include suboptimal foraging trajectories, energetic expenditures, and the physiological toll of social subordination.

To systematically dissect these phenomena across taxa, this report categorizes the empirical evidence into three distinct analytical layers: *physiology* (the measurable biological, neurobiological, and demographic parameters underlying decision-making architectures), *behaviour* (the statistical and probabilistic actions of populations, characterized by overlapping distributions and game-theoretic interactions), and *culture* (the variable, socially transmitted institutions and norms that scale these behaviours). This framework provides a rigorous foundation for comparative analysis across mammalian taxa, including humans, drawing explicitly upon peer-reviewed primary literature, systematic reviews, and meta-analyses to evaluate the origins, mechanisms, and future outlooks of mammalian leadership.

Layer 1: Physiology (Measurable Foundations of Leadership)

The capacity for leadership and collective decision-making in mammals is fundamentally constrained and facilitated by measurable physiological parameters. These include demographic life-history traits, the neurobiological mechanics of spatial processing, epigenetic regulation, and the endocrine responses to social stress.

Life-History Demographics and Post-Reproductive Survival

In several highly social, long-lived mammalian species, demographic physiology strictly dictates the emergence of leadership structures, particularly during periods of ecological severity. The most striking empirical evidence emerges from species exhibiting prolonged post-reproductive lifespans, a rare physiological trait observed primarily in humans, short-finned pilot whales (*Globicephala macrorhynchus*), and killer whales (*Orcinus orca*)[1]. Brent et al. (2015, *Current Biology*) conducted an exhaustive longitudinal study on resident killer whales in the North Pacific, examining a sample size of 589 recorded whales over three decades[1]. The physiological cessation of reproduction in female killer whales—often occurring in their 30s or 40s, while their maximum lifespan extends into their 90s—fundamentally shifts their evolutionary imperative from direct reproductive competition to the maximization of

inclusive fitness via kin support[1]. Brent et al. (2015) established that the survival of grandoffspring was highly dependent on the physiological presence of a post-reproductive grandmother[3].

The reported effect size was substantial: the mortality hazard ratio for a calf losing a maternal grandmother was 4.5 times higher in the two years following her death compared to calves with living grandmothers[1]. Crucially, this mortality risk increased by a factor of 1.5 if the grandmother was post-reproductive rather than reproductively active, yielding a total hazard ratio 6.7 times higher during years when the salmon index (a measure of ecological resource availability) was critically low[1]. This physiological reality—the transition out of reproductive competition—allows older females to serve as repositories of ecological knowledge, reliably assuming leadership positions during collective movements to foraging grounds specifically when environmental hardships threaten the pod's survival[1]. This finding has heavily replicated the underlying evolutionary logic of the "grandmother hypothesis" across long-lived mammalian taxa.

Epigenetic Foundations and Neurobiological Spatial Processing

The physiological architecture of decision-making is further governed by epigenomics and neurobiology. A comparative analysis by Smith et al. (2023, *The Innovation*) generated epigenomic data from 13 mammalian species, demonstrating that DNA methylation in promoters and noncoding elements strongly correlates with species-specific traits, including body patterning and social-behavioural phenotypes[6]. Genomic imprinting, functioning through the binding of specific transcription factors during embryonic development, establishes the physiological baseline upon which social behaviours are subsequently built[6].

At the immediate neurobiological level, collective decision-making is rooted in how the mammalian brain processes spatial options and directional vectors. Research utilizing immersive virtual reality across multiple taxa has revealed that animal brains spontaneously reduce complex, multi-choice spatial environments into a series of sequential binary decisions[7]. As modeled mathematically and verified empirically, the physiological constraints of the brain's neural "ring attractors" force a spontaneous geometric bifurcation during movement[7]. When an animal is presented with two distinct movement vectors separated by less than a 90-degree angle, the neurological sensory-motor response automatically computes an average of the vectors, leading to a compromise in physical trajectory[7]. However, when the angle of conflict exceeds 90 degrees, the neural circuitry can no longer compute a viable average. This forces an abrupt, nonlinear "critical transition" where the organism's physiology spontaneously excludes one option and fully commits to the other[7]. This underlying, hardwired neurological constraint reliably predicts the macroscopic statistical behaviour of entire herds, troops, and flocks, forming the physiological substrate for democratic consensus.

Endocrine Stress Responses and Conflict Management

The physiological stress response, measurable via circulating or excreted glucocorticoid levels, plays a vital homeostatic role in group cohesion and conflict resolution. In African elephants (*Loxodonta africana*), McComb et al. (2011, *Proceedings of the Royal Society B*) and related physiological monitoring demonstrated that faecal glucocorticoid metabolite (fGCM) levels

vary significantly based on social integration, herd size, and the age of the matriarch[11]. Utilizing a sample of 145 faecal samples from 123 identified adult females, researchers found that fGCM levels negatively correlated with the number of adult females in a herd, indicating that larger, stable social networks buffer physiological stress[11].

Unresolved conflict within mammalian groups chronically elevates stress hormones, which carry severe long-term immunosuppressive and reproductive costs. The physiological imperative to reduce post-conflict allostatic load forms the biological foundation for reconciliation behaviours. Mammals are biologically driven to rapidly repair damaged relationships to return endocrine profiles to homeostatic baselines, ensuring that the physiological costs of group living do not outweigh the benefits of predator defence and cooperative foraging.

Layer 2: Behaviour (Statistical and Overlapping Distributions)

Behavioural data in wild mammalian populations reveal that leadership and decision-making are rarely characterized by absolute, despotic command. Instead, they operate on overlapping statistical distributions where influence is probabilistic, heavily context-dependent, and frequently democratic.

Collective Movement and Shared Decision-Making

The traditional paradigm of animal behaviour long assumed that dominant individuals—such as alpha males or elder matriarchs—unilaterally dictated the movements of the group. However, high-resolution empirical data consistently demonstrate that collective movement relies on democratic, shared decision-making rules, wherein the statistical properties of the group override individual dominance hierarchies.

Strandburg-Peshkin et al. (2015, *Science*) tested this dynamic in a troop of wild olive baboons (*Papio anubis*) in Kenya. The researchers fitted 25 individuals (representing 80% of the adult and subadult troop members) with custom GPS collars sampling at 1 Hz[13]. The continuous, simultaneous monitoring of relative movements over the course of daily activities yielded a robust, high-throughput sample of movement initiations[13]. The statistical analysis conclusively rejected the hypothesis that dominant individuals monopolize movement decisions. Instead, probability distributions showed that baboons are significantly more likely to follow a movement initiation if multiple initiators agree, irrespective of the initiators' social rank[10].

When conflicts arose—such as two subgroups initiating movement in different directions—the troop's response depended precisely on the neuro-geometric constraints discussed in Layer 1. If the angle of conflict was small (under 90 degrees), the troop compromised and moved in the statistical average of the two directions[10]. If the angle was large, the troop did not split; instead, they probabilistically chose one direction over the other, aligning with the majority[10].

Furthermore, a subsequent analysis by Strandburg-Peshkin et al. (2017, *eLife*) revealed that habitat features (such as avoiding dense vegetation or following roads) interact with a strong social preference to occupy spaces recently traversed by troop mates, forming an emergent, cohesive group structure without centralized leadership[15]. These findings have heavily

replicated the theoretical models of collective motion originally proposed by Couzin et al. (2005, *Nature*), confirming that "uninformed" or non-dominant individuals promote democratic consensus in animal groups[8].

Quorum Sensing and Threshold Mechanics

Consensus often relies on specific numerical thresholds, known as quorum sensing, where the probability of a group committing to an action sharply transitions from linear to exponential once a critical mass of individuals signals agreement.

In African wild dogs (*Lycaon pictus*), Walker et al. (2017, *Proceedings of the Royal Society B*) identified a behavioural quorum mechanism based on highly specific auditory signals. Analysing a sample size of 34 pre-departure "social rallies" in Botswana, the researchers observed that packs essentially "vote" to initiate a collective hunting movement via rapid nasal exhalations, or sneezing[18]. The quorum threshold required for group departure varied by the social rank of the initiator, presenting a system of rank-weighted democracy. If a dominant alpha individual initiated the rally, an average of only 3 sneezes was required from the pack to achieve consensus and depart[18]. However, if a subordinate individual initiated the rally, the quorum threshold rose significantly to approximately 10 sneezes[18]. The effect size demonstrates that while dominants possess heavier voting weight, the collective will of subordinates can consistently override dominant preferences provided their numerical consensus is sufficiently large[19].

Similarly, Meunier, Leca, et al. (2009, *Proceedings of the Royal Society B*) observed precise quorum rules in a semi-free ranging group of white-faced capuchin monkeys (*Cebus capucinus*). Analysing 294 start attempts (111 successful, 183 failed), they found that the probability of a movement succeeding relied on a minimum quorum threshold of exactly three individuals joining the initiator[22]. The decision-making process was distributed rather than concentrated in high-ranking monkeys, relying heavily on a mimetic process: until the threshold of three followers was met, the initiator's likelihood of cancelling the movement was exceptionally high[23].

Leadership by Sex, Age, and Dominance

When evaluating leadership across sex and age demographics, the literature indicates significant species-specific adaptations, largely tied to ecological knowledge and evolutionary kinship structures.

In African elephants, McComb et al. (2001, *Science*) demonstrated that the oldest female matriarchs serve as the primary decision-makers regarding predatory threats. Through a series of playback experiments utilizing lion roars, researchers compared herds led by young matriarchs (mean age ~35 years) with those led by older matriarchs (mean age >55 years)[25]. Older matriarchs were significantly better at discriminating between the roars of single lions versus groups of lions, and between male and female lions, prompting their herds to adopt appropriate, rapid defensive bunching behaviours[26]. The effect size of matriarch age was profound: it served as a primary predictor of reproductive success for the entire family unit, calculated as calves produced per female reproductive year[12].

In equids, the popular anthropomorphic myth of the "lead stallion" or "lead mare" strictly

controlling herd trajectories has been thoroughly dismantled by empirical network analysis. Krueger, Bourjade, et al. (2014, *Behavioural Processes*; 2015, *PLoS One*) analysed collective movements in feral horses (*Equus caballus*) and Przewalski's horses (*Equus ferus przewalskii*)[27]. They delineated two distinct types of movement initiation: "herding" (driving others from behind) and "departure" (walking in front and eliciting following from the herd). While herding behaviour was found to be entirely exclusive to adult alpha males, *any* group member—regardless of sex, age, or dominance rank—could initiate a successful movement by departure[27]. The data revealed extensively overlapping behavioural distributions: while higher-ranking individuals were followed slightly more often on average, no single individual reliably acted as a leader capable of driving the majority of group movements[28].

Conflict Resolution and Post-Conflict Reconciliation

Social mammals inevitably experience intragroup conflict over mates, food, and spatial positioning, which acutely threatens group cohesion. To mitigate these disruptions, species engage in post-conflict affiliation, termed "reconciliation." First identified by de Waal and van Roosmalen (1979) in chimpanzees, reconciliation has been rigorously documented in over 30 primate species, as well as in spotted hyenas, bottlenose dolphins, feral sheep, and domestic goats[32].

The prevailing behavioural framework is the "Valuable Relationships Hypothesis," developed by Aureli and de Waal (2000), which posits that opponents are more likely to reconcile if their relationship holds high value for future cooperation, coalition-building, or resource acquisition[32]. For example, in many macaque and baboon species, female-female dyads (which form the stable, philopatric core of the matrilineal troop) reconcile conflicts at significantly higher rates than male-male dyads, reflecting the immense ecological and reproductive value of female social bonds[38]. Silk et al. (2003, *Science*) demonstrated that female baboons who maintain strong, affiliative social bonds (frequently repaired through post-conflict grooming) experience enhanced longevity and significantly higher infant survival rates[39].

By contrast, in species where male alliances are paramount for territory defence, such as chimpanzees, male-male reconciliation rates are notably high[34]. Sex differences in conflict resolution are thus not rigidly dimorphic across the mammalian class but are highly flexible, tracking the specific ecological and reproductive values of the bonds in question.

Layer 3: Culture (Variable Constructs and Comparative Analysis)

While physiology sets the biological boundaries and behaviour describes the statistical reality of daily interactions, *culture*—defined in evolutionary biology as variable, socially transmitted information, traditions, and institutional structures—shapes how these decision-making mechanisms scale within and across generations.

The Comparative Analysis of Smith et al. (2016)

To understand how human social organization aligns with or diverges from the broader mammalian pattern, Smith et al. (2016, *Trends in Ecology & Evolution*) conducted an exhaustive comparative analysis of leadership across 16 small-scale societies[45]. The sample provided a

robust evolutionary lens, incorporating 8 non-human mammalian societies and 8 small-scale human societies, as detailed below.

Non-Human Mammalian Societies (NHM)	**Small-Scale Human Societies (SSS)**
African elephant (*Loxodonta africana*)	Ache (Paraguay forest)
Bottlenose dolphin (*Tursiops sp.*)	Cheyenne (North American plains)
Chimpanzee (*Pan troglodytes*)	Inuit (Canadian arctic)
Lion (*Panthera leo*)	Kipsigis (Kenyan savannah)
Meerkat (*Suricata suricatta*)	Nootka (Canadian Pacific coast)
Plains zebra (*Equus quagga*)	Pimbwe (Tanzanian woodlands)
Spotted hyena (*Crocuta crocuta*)	Shoshone (North American Great Basin)
White-faced capuchin (*Cebus capucinus*)	Tsimane (Bolivian Amazon)

The analysis evaluated leadership across four distinct functional domains:

1. **Collective Movement:** Organizing group travel, navigation, timing, and direction[46].
2. **Food Acquisition:** Coordinating foraging, hunting, and resource distribution[46].
3. **Within-Group Conflict Mediation:** Resolving intragroup disputes and enforcing norms[46].
4. **Between-Group Interactions:** Directing peaceful or hostile encounters with neighboring out-groups[46].

Leadership within these domains was quantified along five theoretical dimensions: **Distribution (Skew)** (how widely shared decision-making is); **Emergence** (achieved via skill vs. inherited/ascribed); **Power** (the extent of coercive authority); **Relative Payoff** (the fitness or resource benefits gained by the leader); and **Generality** (whether an individual leads across multiple domains or specializes in one)[46].

Human Commonalities and Evolutionary Divergences

The findings revealed profound evolutionary commonalities. In both humans and non-human mammals, leadership in collective movement is generally moderate, democratic, and widely distributed[45]. Conversely, leadership during between-group conflicts and within-group mediation tends to be highly concentrated in specific, dominant individuals across all 16 societies[45]. Furthermore, across the animal kingdom, leadership is largely

"attribute-based"—achieved via experience, physiological state, or age—rather than strictly inherited[45].

However, the cultural layer introduces distinct divergences in humans that fundamentally alter social living:

1. **Generality vs. Role Specialization:** Non-human mammals tend to feature "domain-general" leaders; if an alpha spotted hyena leads in between-group conflict, she is highly likely to also control food acquisition and movement[46]. Human societies rely heavily on "domain-specific" leadership (role specialization), where different individuals lead depending on the specific task (e.g., a dedicated hunt leader distinct from a conflict mediator)[46].
2. **Coercion vs. Persuasion:** Non-human mammalian leaders rely significantly more on physical dominance and coercive power to enforce followership. Small-scale human societies feature leaders who exercise minimal coercive power, relying instead on culturally transmitted prestige, persuasion, and institutional norms[46].
3. **Food Acquisition:** In most non-human mammals, food acquisition and consumption are highly individualized and competitive, even in pack hunters. In human societies, the acquisition and distribution of food is a highly cooperative, shared cultural activity defined by strict equity norms[46].

These divergences suggest that humans possess unique cultural and cognitive mechanisms—specifically syntactic language and high-volume cumulative cultural transmission—that allow them to solve vast coordination problems without resorting to the brute dominance hierarchies seen in non-human taxa[46].

Controversies and Leading Critics

The literature on mammalian decision-making is characterized by intense theoretical debate. Two major controversies currently dominate the field, requiring careful synthesis of competing evidence.

1. The Despotic Leader vs. The Democratic Herd

The Controversy: Historically, primatologists and ethologists assumed that dominant individuals dictated group actions. King and Cowlishaw (2008, *Current Biology*) are leading proponents of the view that, under certain motivational states, dominant individuals can manipulate group movement to their own advantage, asserting a despotic influence that overrides the majority[13]. **The Rebuttal:** Conversely, Couzin et al. (2005, *Nature*) and Strandburg-Peshkin et al. (2015, *Science*) have generated highly replicated datasets showing that "uninformed" or subordinate individuals promote democratic consensus. They argue mathematically that the "wisdom of crowds" (Condorcet's jury theorem) makes shared decision-making inevitable for survival, as pooling information is strictly more accurate than relying on a single, potentially flawed leader[8]. The current consensus leans heavily toward the democratic model: while dominants may occasionally hijack decisions when highly motivated, day-to-day movement is fundamentally governed by democratic vector-averaging and subordinate quorums[10].

2. The Valuable Relationships Hypothesis vs. Costly Signalling and

Security

The Controversy: The Valuable Relationships Hypothesis, championed by de Waal and Aureli (2000), argues that reconciliation functions specifically to repair damaged relationships, predicting that dyads with valuable relationships will reconcile at the highest rates[33]. **The Rebuttal:** Critics, including Rowell (2000) and evolutionary psychologists like M.E. McCullough, argue that this view is insufficient. Observational tests on captive bonobos have found evidence supporting a competing "Relationship Security" hypothesis, which suggests that highly secure, incredibly valuable relationships actually *do not* require explicit reconciliation after a conflict, because a single aggressive interaction is insufficient to damage a robust bond[36].

Furthermore, McCullough et al. (2014, *PNAS*) conducted a longitudinal study with 337 human participants to re-evaluate reconciliation through the lens of costly signalling and exploitation risk. They found that human forgiveness and reconciliation rely heavily on recalibrating the "relationship value" versus the "exploitation risk" of the transgressor[50]. As tested by Ohtsubo et al. (2014, *Evolution and Human Behavior*) across large sample sizes (N=529 and N=311), the efficacy of reconciliation tactics varies by cultural ecology: costly compensation is required to signal genuine intent in highly mobile societies (where exploitation risk is high and individuals can easily flee), whereas simple apologies often suffice in residentially stable communities[53]. Therefore, critics argue that reconciliation is not merely about preserving value, but about mathematically signalling non-exploitation.

Distinguishing Averages from Individuals

A critical error in behavioural ecology—and its subsequent application to human sociology—is the conflation of statistical population averages with individual predictive potential. The literature clearly delineates the two, a distinction fundamentally rooted in statistical variance. To quantify the predictive power of ecological and evolutionary models, Møller and Jennions (2002, *Oecologia*) conducted a meta-analysis of 43 published meta-analyses (encompassing 93 estimates using Pearson's *r* and 136 using Hedges' *d*). They determined that, on average, the main biological factors of interest explained only 2.51% to 5.42% of the variance (r^2) in ecological data[55]. While critics later argued that specific, localized statistical models could explain up to 47-51% of variance when heavily controlled[57], the overarching reality remains: biological and behavioural data are immensely noisy.

Effect Size Measure	Small Effect	Medium Effect	Large Effect	Very Large Effect
Odds Ratio (OR)	1.5	2.5	4	10
Cohen's *d*	0.20	0.50	0.80	1.30

Pearson's *r*	0.10	0.30	0.50	0.70

Table: Standard effect size interpretations utilized in ecological and psychological behavioural meta-analyses (adapted from standard literature conventions)[59].

Consequently, while we can state robust facts about *averages*, these cannot strictly predict *individual* behaviour. For example, in feral horses, 100% of "herding" behaviour is performed by alpha stallions; this is a massive effect size[27]. However, when analysing "departure" leadership, the statistical distribution overlaps entirely across sexes and ages[27]. An individual's immediate physiological state—whether they are hungry, bold, or possess local ecological knowledge—overrides their demographic category. Therefore, while older elephant females make statistically better ecological decisions on average than younger ones[26], one cannot predict the leadership capacity of an *individual* primate, equid, or human solely by their sex or rank without accounting for their individual motivational state, epigenetics, and network centrality.

Summary of Robust Findings

#	Robust Empirical Finding
1	Mammalian collective movement relies fundamentally on shared, democratic decision-making (vector averaging and quorum sensing) rather than despotic command.
2	When directional conflicts arise, neural geometry forces groups to compromise if the angle is small (<90 degrees) and bifurcate probabilistically if the angle is large.
3	Post-reproductive females (e.g., in orcas and elephants) reliably assume leadership roles during environmental crises, utilizing accumulated ecological knowledge to drastically improve kin survival.
4	Quorum thresholds for consensus are often rank-weighted; dominant individuals require fewer followers to initiate group action, but

	unified subordinates can override them.
5	In equids, coercive "herding" is exclusive to males, but movement initiation via "departure" is entirely distributed across sexes and ranks.
6	Post-conflict reconciliation is ubiquitous across social mammals and serves to alleviate physiological stress (lowering glucocorticoids) and maintain group cohesion.
7	Reconciliation rates are highly dependent on the ecological value of the specific relationship (e.g., female-female bonds in macaques and baboons enhance infant survival).
8	Compared to other mammals, human leadership is notably less coercive, relying significantly more on prestige, persuasion, and cultural norms.
9	Human leadership is highly domain-specific (role specialization), whereas non-human mammalian leaders tend to dominate across multiple domains simultaneously.
10	Cooperative food acquisition is a uniquely robust cultural feature of human societies, contrasting sharply with the individualized foraging of most other mammals.

Contested or Open Questions

Topic	**Open Question / Controversy**

Reconciliation Mechanics	Does reconciliation strictly repair damaged relationships (Valuable Relationships Hypothesis), or are the most secure relationships immune to damage and therefore less in need of active reconciliation (Relationship Security)?
Human Egalitarianism	At what exact point in hominid evolutionary history did the capacity for cooperative food acquisition and non-coercive, domain-specific leadership diverge from the primate baseline of rank-based, domain-general dominance?
Dynamic Quorums	How do groups utilizing quorum thresholds (e.g., wild dog sneezes, capuchin mimetic joining) adjust their minimum numerical thresholds dynamically when under immediate predator threat versus casual foraging?
Vector Limitations	While models prove baboons and insects average vectors separated by less than 90 degrees, how do multi-level societies process more than two conflicting vectors simultaneously without fragmenting?
Costly Signalling	To what extent does residential mobility dictate the evolutionary necessity of costly compensation over simple apology in human conflict resolution?

Implications for living together

When extrapolating behavioural ecology and evolutionary biology to human social structures—whether couples, families, organizational boards, or broader societies—one must strictly avoid the naturalistic fallacy: the assumption that because a behaviour is biologically "natural," it is morally "good" or desirable. However, the structural realities of mammalian decision-making provide profound, data-driven insights into how mixed-sex groups optimize cohesion, mitigate stress, and navigate conflict.

First, the overwhelming prevalence of shared, democratic decision-making in navigating spatial and ecological challenges indicates that pooling information yields statistically superior outcomes compared to despotic rule. In human organizations and families, enforcing strict, unilateral authority structures runs contrary to the highly successful mammalian baseline of vector-averaging and quorum sensing. Allowing subordinate or minority voices to initiate movement—and establishing cultural "quorums" for action—harnesses the collective sensory capacity of the group. As seen in baboons and wild dogs, this distributed processing prevents catastrophic errors driven by the informational blind spots of a single dominant individual.

Second, the clear evolutionary utility of post-reproductive female leadership highlights the immense value of ecological and social knowledge over sheer physical dominance. Societies, families, and corporate structures that marginalize older individuals lose access to the "repositories of knowledge" that, in species like elephants and orcas, literally determine the survival of the group during crises. An organizational structure optimized for resilience must formally value experience and historical data retention over aggressive, short-term competitive posturing.

Third, the evolutionary divergence of human leadership—shifting from domain-general physical coercion to domain-specific prestige and persuasion—suggests that modern human environments thrive best on role specialization. Expecting one individual in a couple or an organization to lead across all domains (financial, emotional, logistical, conflict resolution) is a regression to an outdated mammalian baseline. Human structural success relies on dividing leadership dynamically based on immediate competence and situational context.

Finally, the biology of reconciliation reveals that conflict is not an anomaly in social living; it is a mathematical constant. The health of a family or society is not measured by the absence of conflict, but by the efficiency and speed of its post-conflict reconciliation mechanisms. Unresolved conflicts result in chronic allostatic load, elevating stress hormones that degrade long-term physiological and psychological health. Establishing reliable, low-cost signals for apology, alongside costly compensation when exploitation risks are high, is structurally necessary to alleviate physiological stress, maintain cooperation, and secure the long-term

viability of the human group.
