DH-02 Contemporary foragers: division of labour and gender relations

The empirical study of extant mobile hunter-gatherer societies provides a vital window into the parameters of human social organisation, the origins of the sexual division of labour, and the socioecological mechanisms that sustain or erode gender egalitarianism. While contemporary foragers—including the Hadza of Tanzania, the Ju/'hoansi (!Kung) of Botswana and Namibia, the Agta of the Philippines, the Mbendjele BaYaka of the Congo Basin, the Aché of Paraguay, the Aka and Mbuti of the Central African forests, the Batek of Malaysia, the Inuit of the Arctic, and Australian Aboriginal groups such as the Martu—are modern peoples embedded in complex historical trajectories, their reliance on wild resources and mobile band structures offers a unique baseline for understanding human behavioural ecology.

To systematically analyse gender relations in these societies, researchers employ a tripartite analytical framework. This necessitates separating three interacting layers: physiology, which establishes the measurable metabolic and biomechanical boundaries of human bodies; behaviour, which manifests as overlapping statistical distributions representing optimizing responses to local ecologies; and culture, the variable set of norms, institutions, and levelling mechanisms that filter, amplify, or suppress underlying biological asymmetries. Furthermore, analyses must differentiate between typologies of foraging. The most profound egalitarianism is found in "immediate-return" societies (e.g., the Hadza and Ju/'hoansi), where food is consumed rapidly and wealth accumulation is structurally impossible, as opposed to "delayed-return" societies that store surpluses, enabling wealth inequality and heightened gender stratification[1].

Layer 1: Physiology and Energetic Constraints

Physiology dictates the boundary conditions of human energy budgets, life history variables, and physical capacities, establishing the constraints under which the sexual division of labour operates. These physiological realities are measurable and inherently sexually dimorphic, though they interact fluidly with behavioural plasticity.

Biomechanics and Dimorphism

At the biomechanical level, sexual dimorphism in *Homo sapiens* establishes differing comparative advantages for specific physical tasks. Adult males, on average, possess roughly twice the upper-body strength and 66% greater leg strength than adult females[3]. In a foraging context, these average differences confer male comparative advantages in tasks involving maximal burst force, the use of forceful projectiles (such as heavy draw-weight bows), load carriage over extended distances, or close-quarters engagement with large, dangerous animals[3]. Conversely, female reproductive physiology—specifically the extraordinary caloric and biomechanical demands of gestation, lactation, and the transport of highly altricial (dependent) infants—imposes specific constraints on mobility and risk-taking during peak reproductive years.

Constrained Energy Expenditure

The physiological limits of human energetics impose rigid ceilings on caloric expenditure. It was long assumed that highly active hunter-gatherers expended vastly more calories daily than sedentary populations in industrialized nations. This assumption was overturned by Pontzer and colleagues in a landmark 2012 study published in *PLoS ONE*[4]. Using the gold-standard doubly-labeled water method, the researchers measured the total daily energy expenditure (TEE) of 30 Hadza adults (17 women, 13 men)[4].

The results established the "constrained energy expenditure" hypothesis. While the physical activity level (PAL) of the Hadza was significantly higher than that of Westerners (averaging 1.78 for Hadza women and 2.26 for Hadza men), their absolute daily energy expenditure was virtually identical to Western populations when controlling for lean body mass[5]. Hadza women burned an average of 1,877 kcal/day, and Hadza men burned 2,649 kcal/day[4].

Population (Sample Size)	**Sex**	**Mean Mass (kg)**	**BMI (kg/m²)**	**Body Fat %**	**TEE (kCal/day)**	**PAL (TEE/BMR)**
Hadza (N=17)	Female	43.4 ± 6.4	20.2 ± 1.7	20.9 ± 4.6	1877 ± 364	1.78 ± 0.30
Hadza (N=13)	Male	50.9 ± 5.4	20.3 ± 1.3	13.5 ± 4.2	2649 ± 395	2.26 ± 0.48
Western Farming (N=14)	Female	48.1 ± 6.9	20.7 ± 3.2	27.3 ± 5.3	2469 ± 315	2.11 ± 0.30
Western Farming (N=11)	Male	54.7 ± 2.9	21.2 ± 1.6	16.0 ± 3.3	2855 ± 435	2.08 ± 0.26
Data derived from Pontzer et al. (2012) demonstrating constrained						

metaboli c ceilings despite high physical activity. Note: BMR refers to Basal Metaboli c Rate. [cite: 5]						

This physiological ceiling has profound implications for the division of labour. Because total energy expenditure is constrained, individuals cannot simply increase their caloric intake to offset unlimited physical activity; the body engages in "energy trading," down-regulating basal metabolic investments in other systems (such as reproduction or immune function) to accommodate high activity[6]. Therefore, subsistence strategies must optimize caloric returns against strict metabolic limits. For human females, who must fund the energetic costs of pregnancy and lactation within this constrained budget, targeting reliable, low-variance resources often yields the most optimal reproductive outcomes.

The Evolution of Life History

These energetic constraints intersect with the unique trajectory of human life history. In a 2021 study in the *Proceedings of the National Academy of Sciences* (PNAS), Kraft et al. demonstrated that human survival in a skill-intensive foraging niche requires immense intergenerational transfers of energy[8]. Unlike chimpanzees, where offspring independently forage post-weaning, human children remain energetically dependent on adults until their late teens[9]. The physiological demands of a large brain and extended childhood necessitate a cooperative breeding system where male provisioning, female gathering, and alloparental care combine to subsidize caloric deficits. This multi-generational pooled energy budget allows human females to stack multiple dependent offspring simultaneously, a physiological impossibility for other great apes[9].

Layer 2: Behaviour and The Division of Labour

While physiology sets absolute boundaries, human behaviour operates as a set of overlapping statistical distributions. Distinguishing what is known about averages from what can be said about individuals is the most critical analytical step in evaluating the division of labour.
On average, across all ethnographically documented foraging societies, men spend disproportionately more time hunting large, mobile game, while women spend disproportionately more time gathering plant foods, extracting small game, and engaging in

direct infant care. However, these are overlapping bell curves. While the *average* man brings in more meat than the *average* woman, the variance is vast. Many individual women out-produce individual men in daily caloric returns, particularly women who are post-reproductive. Furthermore, the ratio of plant to animal foods varies aggressively by ecology; Inuit populations in the Arctic depend almost entirely on meat and fish, whereas warm-climate foragers consume a roughly 50/50 balance of plants and animals[10]. Behaviour is an optimizing response to local ecology, characterized by immense plasticity.

The 'Woman the Hunter' Controversy

The interpretation of these behavioural distributions recently ignited a highly publicized academic controversy. For decades, the "Man the Hunter" paradigm dominated anthropology, positing that male big-game hunting was the primary evolutionary catalyst for human cognition, cooperation, and social structure, effectively relegating female labour to a passive, secondary role[12].

Seeking to dismantle this paradigm, Anderson and colleagues published a 2023 study in *PLoS ONE* titled "The Myth of Man the Hunter: Women's contribution to the hunt across ethnographic contexts"[3]. The authors queried D-PLACE (Database of Places, Languages, Culture and Environment), starting with 391 foraging societies and narrowing the sample to 63 societies containing "explicit" descriptions of hunting[3]. They reported a staggering effect size: in 50 of those 63 societies (79%), women were reported to hunt, and in 33% of those cases, women actively pursued large game[16]. Anderson et al. concluded that the gendered division of labour was a myth, arguing that female hunting was a normative, widespread feature of foraging economies.

This claim failed to replicate under rigorous scrutiny and was immediately challenged. In 2024, a coalition of leading hunter-gatherer behavioral ecologists—including Venkataraman, Hames, Hagen, and Kramer—published a comprehensive empirical rebuttal in *Evolution and Human Behavior* (with preprints on *bioRxiv*)[16]. Venkataraman et al. explicitly detailed severe methodological flaws in the Anderson study, primarily a massive sample-selection bias. By intentionally narrowing a dataset of 391 societies down to 63 specifically by searching for texts detailing hunting strategies, the original authors artificially inflated the prevalence estimate[3]. Furthermore, Venkataraman et al. identified pervasive coding errors: Anderson et al. utilized a binary "presence/absence" variable for hunting, collapsing fundamentally distinct behaviours—such as women accompanying men on hunts, carrying butchered meat, or capturing small animals opportunistically while gathering—into the exact same category as intentional big-game stalking[14].

The leading critics noted that approximately 35% of the 63 societies cited by Anderson could not even be located in the primary D-PLACE database as coded[3]. The strongest evidence on this controversy demonstrates that while female foragers absolutely do hunt in specific contexts (such as the Agta and the Matses), the gendered division of labour remains an empirical reality in every known contemporary hunter-gatherer society[16]. Venkataraman et al. cautioned against ethnographic revisionism, noting that projecting Westernized, contemporary political conceptions of labor equality onto the past diminishes the vital, complementary nature

of female foraging and downplays the severe trade-offs women face regarding infant care and energetics[18].

High-Yield Female Foraging: Martu and Optimal Foraging Theory

Recognizing the statistical reality of the division of labour does not minimize female economic contributions; rather, it allows for a precise understanding of distinct foraging logics. The strongest quantitative evidence of highly specialized, high-yield female hunting comes from the work of Bliege Bird, Bird, and Codding among the Martu of Australia's Western Desert, published across studies in *American Antiquity* (2005, 2012, 2017)[19].

Martu society features a female-biased foraging economy, where women bring in the majority of total kilocalories[22]. Utilizing anthropogenic fire to clear spinifex grass, Martu women track and extract small game, primarily sand monitor lizards[21]. Optimal Foraging Theory (OFT) historically assumed that prey body size was the primary determinant of post-encounter return rates (kcal/hr-handling)[20]. However, Bliege Bird et al. demonstrated that for the Martu, prey size is not a reliable predictor of returns[19]. Small goannas and lizards offer exceptionally high, reliable return rates because pursuit failure is rare.

Male Martu, conversely, target larger, highly mobile game (such as kangaroos and introduced camels)[23]. This male strategy yields massive caloric packages when successful, but suffers from high pursuit failure rates and immense daily variance[20]. Martu women optimize for predictability, trading the prestige of a large-game kill for the certainty of provisioning their children and maintaining cooperative kin networks. This demonstrates that the division of labour is an economic optimization strategy, where overlapping distributions of male and female behaviour operate to balance high-variance/high-yield hunting with low-variance/reliable gathering and small-game extraction[21].

The Grandmother Hypothesis

The behavioural optimization of female foraging extends significantly across the lifespan, providing the foundation for one of the most important theories in human evolution: The Grandmother Hypothesis. Developed by Hawkes, O'Connell, and Blurton Jones based on extensive time-allocation and return-rate data collected among the Hadza in the 1980s and 1990s, this model explains the evolutionary paradox of female menopause[26].

In papers published in *Current Anthropology* (1997) and *Oecologia* (1998), Hawkes and colleagues noted that human females possess a uniquely long post-reproductive lifespan compared to other primates.

Species	Average Adult Lifespan	Age at Maturity	Age at Weaning	Maximum Lifespan
Orangutans	17.9 years	14.3 years	6.0 years	~50 years
Gorillas	13.9 years	9.3 years	3.0 years	~50 years

Chimpanzees	17.9 years	13.0 years	4.8 years	~50-60 years
Humans (Foragers)	32.9 years	17.3 years	2.8 years	~90-100 years
Comparative primate life history variables. Humans display early weaning but extended post-reproductive survival, uniquely supported by alloparental provisioning. (Data derived from Hawkes et al. 1998). [cite: 27, 28]				

Among the Hadza, deeply buried tubers constitute a vital dietary staple. However, extracting these tubers requires strength and skill that weaned children do not possess[26]. Hawkes et al. documented that post-menopausal Hadza women achieve some of the highest caloric return rates in the society[27]. By subsidizing the caloric needs of their weaned grandchildren, grandmothers absorb the energetic burden of child-rearing. This alloparental subsidy allows their own daughters to cease lactational amenorrhea earlier, dramatically shortening interbirth intervals[27]. Consequently, evolutionary selection favored genes for post-reproductive longevity because robust older women directly increased their inclusive fitness through their daughters' accelerated reproductive rates[9]. This robust finding fundamentally counters the male-centric view of human life history, positioning older women as the primary economic engine driving the evolution of extended human lifespans.

Layer 3: Culture, Egalitarianism, and Social Organization

While physiology establishes constraints and behaviour optimizes returns, culture acts as the variable mechanism that manages power dynamics. In immediate-return foraging societies,

egalitarianism is not a passive, natural state of grace; it is an aggressively maintained cultural architecture designed to suppress dominance and enforce equality. Through mechanisms such as "demand sharing"—where hunters are obligated to distribute meat upon request—and ritualized ridicule of successful hunters (designed to deflate ego), groups like the Ju/'hoansi actively sever the link between physiological prowess and political authority.

Bilocality and the Expansion of Social Networks

The cultural rules governing post-marital residence are the primary engine of hunter-gatherer social structure. In a highly influential 2015 study published in *Science*, Dyble, Migliano, Page, Salali, and colleagues resolved a major paradox regarding human cooperation[31]. Evolutionary theory dictates that organisms should preferentially live and cooperate with kin (inclusive fitness)[31]. Yet, ethnographic data reveal that contemporary hunter-gatherer camps exhibit remarkably low within-camp genetic relatedness, comprising a high proportion of unrelated individuals[31].

To investigate this, Dyble et al. collected genealogical and residential data from 1,863 dyads among the Mbendjele BaYaka (Congo) and 4,055 dyads among the Palanan Agta (Philippines), comparing them to a dataset of 1,049 dyads from the Paranan, a patrilocal farming population[31]. They developed an agent-based computer model simulating camp assortment under two conditions: a non-egalitarian condition where only one sex dictated residence, and an egalitarian condition where husbands and wives exerted equal influence[31].

The model demonstrated mathematically that when both sexes have an equal say—and both attempt to maximize the number of their own kin in a camp—the inevitable statistical outcome is a dilution of overall camp relatedness[31]. This sex-egalitarian bilocality (fluid movement between the husband's and wife's kin networks) prevents the formation of localized, highly related fraternal or sororal interest groups.

The evolutionary implications are profound. By reducing within-camp relatedness, sexual equality drastically increases the number of distinct camps in which any individual has at least one primary kin member[35]. This creates an expansive, interconnected meta-network across the landscape. This widespread social network serves as a buffer against localized ecological failures and facilitates the transmission of cumulative culture and technological innovation[31]. Egalitarian gender relations were therefore not merely a moral byproduct, but a foundational selective advantage in human evolutionary history.

Bargaining Power and the Division of Leisure

If males and females possess equal political voice but engage in different types of labour, how are domestic workloads negotiated? In industrialized societies and agricultural economies, inequalities in income or property ownership frequently result in skewed distributions of domestic labour. Microeconomic Nash bargaining models predict that an individual with better "outside options" (fallback security if the marriage dissolves) will leverage that advantage to negotiate for more leisure time and fewer domestic chores[38]. In modern Western settings, this often results in women undertaking 70% to 90% of household chores[39].

A 2024 study by Deb, Dyble, Page, Salali, Migliano, Chaudhary, and colleagues in *Evolution and Human Behavior* tested this bargaining hypothesis among the Agta and the Mbendjele

BaYaka[38]. In these immediate-return societies, material wealth is non-existent; therefore, a person's "outside option" is dictated by their social capital—the number of non-kin campmates willing to share resources with them[38].

Using Bayesian multilevel logistic regression and focal follows of individuals from 6 AM to 6 PM over several weeks, the researchers tracked the division of labour and leisure[38]. The findings decisively contradicted the predictions of the bargaining model: there was no statistical association between an individual's social capital and their share of leisure time[38]. Instead, the researchers documented a "remarkable equality in the division of leisure time within households"[38]. Despite variations in individual popularity or caloric production, husbands and wives enjoyed statistically identical amounts of leisure time[39].

This finding underscores the power of the cultural layer. In immediate-return foragers, robust sex-egalitarian norms, combined with the non-substitutability of male and female subsistence labour, actively suppress the translation of individual social advantage into domestic exploitation[38]. Assertive egalitarianism neutralizes what would otherwise become patriarchal or matriarchal dominance. Furthermore, decision-making at the camp level operates on consensus; as Dyble et al. (2024) note, this high viewpoint diversity and inclusive deliberative norm acts as a coordination game that maximizes collective intelligence[40].

Fatherhood, Sexual Autonomy, and Marriage

The egalitarian ethos extends deeply into reproduction and family structure. While mothers universally provide the majority of direct infant care, forager fathers exhibit some of the highest levels of paternal investment among mammals. Hewlett's (1991) foundational research among the Aka of the Central African Republic demonstrated that Aka fathers hold infants up to 4 months of age for 22% of the time they are in camp, and are responsible for 15.8% of all direct infant care[42]. This high level of intimate paternal care is facilitated by the cooperative nature of the net-hunting economy, where men and women forage together, blurring spatial segregation[44].

Because women retain absolute access to their own kin (bilocality) and are highly productive foragers, they possess substantial economic independence. Ember and Ember (2019) document that premarital and extramarital sexual restrictiveness is tightly correlated with social complexity and wealth inequality; in egalitarian foraging societies without inherited property, female sexual autonomy is exceptionally high[46].

This autonomy is directly reflected in divorce rates. In a 2003 analysis in *Evolutionary Anthropology*, Marlowe documented that serial monogamy is the statistical norm among foragers. Among the Hadza, only roughly 20% of adults remain married to their first spouse for their entire lives[47]. Similar frequencies are observed elsewhere, with 25% of all Aka marriages and 18% of Agta marriages ending in divorce[48]. The lack of structural barriers to divorce ensures that pair-bonds must be maintained through continuous mutual investment and affection, rather than economic coercion. If a marriage becomes abusive or unsatisfactory, a woman simply relocates to the camp of her kin.

Violence, Mortality, and the Limits of Egalitarianism

It is a common error to conflate structural egalitarianism with total pacifism. The absence of hierarchical authority means there is no formal mechanism (e.g., police or courts) to adjudicate disputes. Consequently, interpersonal conflicts can rapidly escalate into lethal violence.
The debate over the baseline of human violence heavily references ethnographic data. Steven Pinker, utilizing data from Richard Lee's 1979 ethnography *The !Kung San*, argued that pre-state societies were highly violent[49]. Lee documented 25 cases of homicide among the Ju/'hoansi between 1920 and 1970[49]. Calculating this against a mean population of 1,500 yielded a homicide rate of 33.3 to 40 per 100,000 person-years—levels comparable to the most violent American inner cities of the 1970s[49]. Lee noted that 23% of these homicides were triggered by sexual jealousy[52].
Similarly, Hill and Hurtado (1996) documented extraordinary rates of adult mortality due to conspecific violence among the pre-contact Aché of Paraguay[53]. The Aché faced immense extrinsic mortality risks from internal club-fights and external raids, which profoundly suppressed their life expectancy at birth to approximately 30-35 years (though individuals surviving childhood routinely reached their 70s)[53].
However, the statistical context of these figures is critical. As Lee subsequently clarified, while the rate per 100,000 appears high due to the tiny population denominator, the 25 Ju/'hoansi homicides over a 50-year period accounted for only 1.0% to 1.6% of total overall mortality[49]. This drastically contradicts claims by the "bellicose school" that 15% to 50% of hunter-gatherers die violently[49].
Furthermore, violence is not a uniform biological absolute. The Batek of Malaysia, documented extensively by Kirk Endicott, possess an absolute cultural abhorrence for violence. When threatened by external enemies, their default strategy is to flee into the forest. Interpersonal physical coercion is socially intolerable, resulting in an environment where Batek women are entirely free from the threat of intimate partner violence[55].
These contrasting ethnographic realities yield a robust conclusion: violence in hunter-gatherer societies is largely driven by interpersonal disputes (reproductive competition) rather than organized warfare over resources[57]. Egalitarian societies manage these stresses primarily through mobility. When tensions rise, bands undergo fission, and antagonists physically separate. Homicide rates escalate non-linearly when ecological constraints (e.g., being tethered to a large permanent waterhole during a drought) prevent this spatial separation[58].

Demographic Plasticity and Sex Ratios

High rates of extrinsic mortality (death beyond parental control, via violence, disease, or predation) act as severe selective pressures, triggering plastic demographic responses. Evolutionary anthropologists have long noted skewed juvenile sex ratios in several foraging populations.

Population	Juvenile Sex Ratio (# males / # females)	Ratio
Agta (Palanan)	281 / 217	1.29

Aché	55 / 36	1.53
Aka	160 / 139	1.15
Batek	31 / 18	1.72
Ju/'hoansi (Central !Kung)	49 / 43	1.14
Selected juvenile sex ratios in foraging populations demonstrating severe male biases. Data derived from Page, Dyble et al. (2019). [cite: 59]		

Among the Palanan Agta, Page, Dyble, and colleagues documented a heavily skewed juvenile sex ratio of 1.29 (129 males per 100 females)[59]. Historically, anthropologists frequently attributed such skews to systematic female infanticide or selective neglect, driven by a cultural preference for male hunters[59]. However, Page and colleagues found an absolute lack of ethnographic evidence for female neglect among the egalitarian Agta[59]. Instead, they hypothesized a biological mechanism: a facultative alteration of the sex ratio at birth. Because human males are universally more vulnerable to early mortality than females, mothers in high-extrinsic-mortality environments may biologically skew conceptions or in-utero survival to produce more males, ensuring that a sufficient number survive to reproductive age to maintain population stability[59]. This highlights that human demographic architecture is not static, but highly responsive to the stress of the socioecological niche.

Conclusion

Summary of Robust Findings:

1. The sexual division of labour is an empirical reality across all documented contemporary foraging societies, driven by physiological constraints, energetics, and the pursuit of comparative advantages.
2. The assumption that female foraging is evolutionarily secondary is false; female extraction of small game (Martu) and tubers (Hadza) provides high-yield, reliable caloric baselines that fund human life history.
3. Total daily energy expenditure (TEE) in humans is physiologically constrained; despite high physical activity, foragers burn a similar number of daily calories as sedentary Westerners, forcing strict caloric trade-offs.
4. Sex-egalitarian bilocality (equal influence over residence) mathematically dilutes within-camp relatedness, driving the formation of the expansive social meta-networks

necessary for cumulative culture.

5. In immediate-return societies, assertive cultural norms enforce a remarkable equality in domestic leisure time, neutralizing disparities in individual social capital or caloric production.
6. Female economic autonomy and bilocal residence guarantee high sexual autonomy and facilitate high rates of serial monogamy, preventing individuals from being trapped in exploitative pair-bonds.
7. While interpersonal violence (often driven by sexual jealousy) occurs and can produce high statistical homicide rates, it accounts for a small percentage of overall mortality and is primarily mitigated through group fissioning and mobility.
8. Grandmothers play a uniquely critical role in human evolution; their high-yield foraging subsidizes the caloric needs of weaned grandchildren, enabling shorter interbirth intervals and driving selection for extended post-reproductive lifespans.
9. Skewed juvenile sex ratios in foraging populations are frequently the result of biological, facultative responses to high extrinsic mortality, rather than culturally mandated female infanticide.
10. Egalitarianism is not a passive state of nature but an aggressively maintained cultural architecture designed to suppress dominance and enforce resource sharing.

Contested or Open Questions:

- **The Granularity of Female Hunting:** While the Anderson (2023) claim of 79% prevalence was heavily contested for methodological flaws by Venkataraman (2024), standardizing the ethnographic coding to determine the exact cross-cultural caloric contribution of opportunistic female hunting versus intentional big-game stalking remains an open challenge.
- **The Directionality of Energetics:** Pontzer's constrained energy expenditure model is debated by physiologists regarding the exact mechanisms by which the body down-regulates basal metabolic rates (BMR) in response to high physical activity without compromising immune or reproductive function.
- **The Primary Driver of Life History:** Evolutionary anthropologists remain divided between the "Grandmother Hypothesis" (post-reproductive female provisioning drives longevity) and the "Embodied Capital Model" (the lengthy learning period required for male hunting of complex, hard-to-acquire resources drives longevity and brain expansion).

Implications for Living Together

An analysis of contemporary foragers demonstrates that human beings are not biologically hardwired for patriarchal dominance, rigid nuclear families, or female subjugation; nor are we naturally peaceful, perfectly harmonious "noble savages." The data reveal that human egalitarianism is an active, fiercely defended cultural achievement.

For modern couples, families, and organizations, the primary implication is that structural conditions dictate the quality of gender relations. Egalitarianism in forager societies is maintained because individuals possess viable "outside options" (expansive kin networks), freedom of movement (divorce and camp fissioning without stigma), and a strict cultural refusal to let economic productivity dictate social authority. When modern societies tether women to localized, patriarchal wealth—or strip away the communal alloparenting networks that historically subsidized the extraordinary metabolic costs of human motherhood—inequality is the inevitable structural result. To foster egalitarian living in contemporary settings, organizations and societies must design architectures that mimic forager structural autonomy: ensuring economic independence, facilitating robust, multi-generational community support networks for child-rearing, and actively cultivating cultural norms that ridicule the hoarding of power and resources. Natural does not mean good, but understanding our evolutionary socioecology provides an empirical blueprint for how power can be successfully dispersed and mutual autonomy maintained.
